Abstract

Since 2010, there has been an approximate annual increase of 1% in CO₂ emissions due to buildings. The reduction of energy consumption and consequently the mitigation of Greenhouse Gases are global goals due to the global issue of climate change. A key step in achieving these goals is to improve the energy performance of buildings, thereby reducing energy consumption and emissions generated by the built environment. In this regard, the present research focuses on identifying and estimating strategies to reduce energy consumption in buildings known as Community Police Units (UPCs) located in the city of Guayaquil, which corresponds to a very hot and humid climate zone. The study consists of statistical analysis of the historical energy performance of 43 buildings sharing the same architectural design. Additionally, the selection of a representative building was made for energy use monitoring and energy simulation. The results revealed a potential saving of 16 000 kWh per year by reducing the control temperature of the air conditioning system by 1°C and adjusting the on/off schedule. This is equivalent to 1 150 USD and 5 metric tons of CO₂ emissions.

Index terms— public service buildings, Energy Efficiency, Energy Savings, Energy Monitoring and simulation

Resumen

Desde el 2010 existe un incremento aproximado del 1% anual respecto a las emisiones de CO₂ a causa de los edificios. La disminución del consumo energético y consecuentemente la mitigación de los Gases de Efecto Invernadero son metas a nivel mundial debido a la problemática global del cambio climático. Un paso clave para alcanzar estas metas es mejorar el desempeño energético de las edificaciones y de esta manera reducir la energía consumida y las emisiones generadas por el parque edificado. En este sentido, la presente investigación se centra en identificación y estimación de estrategias para reducir el consumo de energía de los edificios llamados Unidades de Policía Comunitaria (UPC) localizadas en la ciudad de Guayaquil, y que corresponde a una zona climática húmeda muy calurosa. El estudio está compuesto por el análisis estadístico del rendimiento energético histórico de 43 edificios, que comparten el mismo diseño arquitectónico. Además, se realizó la selección de un edificio representativo para el monitoreo del uso de energía y simulación energética. Los resultados evidenciaron un potencial de ahorro de 16 000 kWh al año, al disminuir 1°C la temperatura de control del sistema de climatización y modificando el horario de encendido y apagado. Esto es equivalente a 1 150 USD y 5 toneladas equivalentes de CO₂.

Palabras clave— Edificios de servicios públicos, Eficiencia Energética, Ahorro de Energía, Monitoreo y Simulación Energética.

1. INTRODUCTION

At a global level, in all regions, the increase in extreme heat events has led to human mortality and morbidity. These phenomena have been caused by the expansion of urban areas, the rise in extreme temperatures, and demographic transformations [1]. It is estimated that the ambient temperature will increase by an average of 1.5°C over the next 20 years [2], which represents an increase in energy demand to achieve comfort conditions in the buildings.

Ecuador is one of the countries geographically located in the tropical zone. This geographical zone is clearly defined as the region located between the tropic of Cancer and the tropic of Capricorn. A small annual temperature range is characteristic of the tropics. Near the equator, the difference in average temperature between the warmest and coldest months rarely exceeds 4°C, and in some places, it is less than 1°C. Annual temperature ranges increase as one moves away from the equator, even at the boundaries of the tropical zone; few locations have an annual range greater than 15°C [3]. The world experienced a net temperature increase between 1961 and 2018 of nearly 1°C from the baseline. During this period, the average warming in the tropics was 0.7°C, as was the case in South America [4].

This zone is characterized by high temperatures and high levels of humidity, which are likely to increase with climate change [5]. Based on current policies, the installed capacity of cooling equipment globally is projected to triple between now and 2050, leading to more than a doubling of electricity consumption [2]. It is crucial to consider that the refrigerants used in cooling systems can vary, including CFCs, HCFCs, HFCs, among others. HFCs, like their predecessors, CFCs and HCFCs, are predominantly used as refrigerants in air conditioning and refrigeration equipment. These substances are potent greenhouse gases. Although HFCs currently account for around 1% of total global Greenhouse Gases emissions, their global warming potential can be hundreds to thousands of times greater than that of CO₂ per unit mass. During the operation, maintenance and disposal activities of equipment using these types of refrigerants, leaks are common, directly contributing to atmospheric warming [6]. In this sense, there is a need to consider energy efficiency strategies to decrease the energy consumption of the active cooling systems without compromising the thermal comfort of the occupants.

Pickering E, et al [7], analyzed six commercial buildings and identifies various building characteristics, including the potential for savings of over 700 MWh valued from building rescheduling alone, it is shown that there is an apparent spike in usage at approximately 6h00, indicating a scheduled Heating, Ventilation, and Air Conditioning (HVAC) event (i.e. pre-cooling) by the building management system, followed by a sharp decrease, showing the tendency for the HVAC units to

overshoot demand and drop in usage. The analysis shows that the addition of unoccupied set point states would drastically alter the consumption and save significant amounts of energy in nighttime/baseload and weekend operation. This demonstrated the potential impact of no-cost energy efficiency measures on the energy consumption of buildings with specific activities.

This research aims to study, identify and estimating strategies to reduce energy consumption in buildings known as Community Police Units (UPCs) located in the city of Guayaquil, which corresponds to a very hot and humid climate zone. Each UPC has jurisdiction to deploy police services in a 1 km² radius area. Currently, Guayaquil has 104 UPCs; however, the data were collected from 43 UPCs built in the last four years. They have similar infrastructure, as well as the same materiality.

The difference is that some have more glass coverage, and the area varies according to the services. Therefore, they were classified as type A and B. The objective of this research is to establish a baseline on the energy performance of these buildings and identify the parameters that affect the thermal behavior and energy consumption of the UPC.

2. METHODOLOGY

The research is developed under the four-stage approach:

- a) Selection and characterization of the sample analyzed,
- b) Characterization of energy consumption and analysis of the influence of environmental temperature on energy consumption
- c) Energy simulation.
- d) Energy monitoring and identification of savings opportunities

2.1 Selection and characterization of the sample

For the study, were selected 43 security buildings built in Guayaquil city in 2014. The selected sample is located randomly over the city as shown in Fig. 1. The city is located in a very hot humid climate zone, considered as an extreme climate zone in Ecuador [8]. According to the Köppen-Gaiger climate classification, Guayaquil belongs to the Aw group (tropical savannah climate) [9]. In addition, it has influence of marine currents from the Pacific Ocean. It is located at 25 m.a.s.l. with an average temperature of 26 °C.

UPCs have similar characteristics. They present a standardized design in their structure and materials. Although, its difference is that some have a higher percentage of glass and the area differs according to the services. Therefore, they were classified as type A and B (see Fig. 2 Fig. 3). Typology A has a construction area of 225 m² and typology B of 200 m². Fig. 4 shows the

architectural simulated model of the buildings that was provided by the Works Contracting Service of Ecuador (SECOB, n.d.).

2.2 Characterization of energy consumption and analysis of the influence of environmental temperature

The database monthly electricity consumption that was used corresponds to the years 2016 and 2017, was provided by the Regulatory Agency for the Control of Energy and Non-Renewable Natural Resources (ARCERNNR for its acronym in Spanish).

The energy use intensity EUI was defined from this information. It is defined as the ratio between the annual energy consumed and the total construction area [10] as shown in (1):

$$EUI = \frac{\text{Energy consumption (kWh)}}{\text{Gross floor area (m}^2\text{)}} \quad (1)$$

The EUI is considered an indicator of energy use that allows buildings to be compared. The characterization of energy consumption in buildings is done through a frequency distribution analysis of the EUI of the total sample.

Considering that the energy consumption of the air conditioning systems is highly influenced by the environmental temperature [11]. It is necessary to know the correlation that exists between these factors (consumption and environmental temperature), in order to define whether the greatest amount of energy consumed is due to a base load independent of temperature (energy related to lighting, office equipment, etc.) or if there is a high degree of influence of environmental temperature on the energy consumption of the building. This analysis allows knowing the energy consumption of the building depending on seasonal changes [11].

Figure 1: Location of 43 buildings

Figure 2: UPC Typology A

Figure 3: UPC Typology B

Figure 4: Architectural model type (a) and (b)

To identify the influence of environmental temperature on energy consumption, the two variables were correlated, finding increasing relationships with a pronounced inclination. The relationship between ambient temperature and energy consumption was defined by a linear regression model finding a coefficient of determination (R²) [12] between 0.4 and 0.7. The Environmental Protection Agency (EPA) states that the minimum R² is 0.4 for simple adjustment ratios and 0.7 for more complex relationships [13]. This analysis allows identifying in a general way the type of energy efficiency measures that can be applied to reduce consumption.

2.3 Energy simulation

The simulation allows analyzing and determining the thermal behavior of the building under real environmental conditions, in order to estimate the electrical consumption. To carry out the simulation, the design builder software was used and the following was considered:

Building design and use: The building is divided into two floors with independent income. On the ground floor of the building are: complaint reception area, office, two bathrooms, warehouse, rack, meeting room, dining room, laundry, rake and domestic gas room. On the first floor there are: bedrooms for men and women (only the women's room has a private bathroom), common bathroom (with showers) and common area.

Building materials: 150 mm concrete block walls with internal and external stucco and paint coating, 200 mm concrete slab roof, 6 mm single glass windows and metal exterior doors with the exception of the main glass entrance. Thermal properties of the envelope elements are shown in Table 1.

The weather data for the 2016-2017 period of Guayaquil city were imported in the format (.epw) Energy Plus which is compatible with Design Builder. Table 2. shows the considerations of occupation of the building. The simulation was calibrated in order to approximate the model to the real energy consumption and the conditions of user behavior [14].

2.4 Energy monitoring

To accurately capture data on real electricity consumption, a comprehensive monitoring system was installed at the primary distribution panel of the UPC, as depicted in Fig. 5. The system comprises JANITZA current transformers, specifically model IPA40.5, coupled with a JANITZA energy meter, model UMG 103-CBM, and a DEXMA datalogger, model DXHW-DEXGATE.

Furthermore, ambient temperature measurements were conducted utilizing a weather station situated within the socio-housing development 1 in Guayaquil, as illustrated in Fig. 6. The employed sensor is a VAISALA model HMP155, meticulously equipped with a solar radiation shield for optimal precision.

Table 1: Thermal properties of envelopment materials [15], [16]

Element	Material	Thermal conductivity [W/m °C]	Density	Specific heat	Solar absorptance	Emissivity	Thickness
			[kg/m³]	[J/kg °C]			[mm]
Roof	Concrete slab	1.4	2 100	840	0.6	0.9	200
Walls	Concrete blocks	0.19	600	1 000	0.6	0.9	150
	Stucco [10]	0.72	1 760	840	0.6	0.9	1
Windows	Glass	0.9	-	-	-	0.84	6

 **** It is considered as air conditioning equipment type split no fresh air

Figure 5: Energy monitoring system

Figure 6: Weather Station

2.5 Identification of savings opportunities

From the findings presented in the preceding sections, passive strategies were discerned for reduce electricity consumption, and the associated savings were estimated. To do this, an electricity rate of 0.072USD/kWh for community service buildings low voltage [17] and an emission factor for electricity use of 0.092tCO₂/MWh [18] were chosen.

3. DISCUSSION AND RESULT ANALYSIS

3.1 Characterization of energy consumption and analysis of the influence of environmental temperature

Fig. 7 shows the characterization of energy consumption of the two typologies which was calculated using (1). It was found that the average EUI in 2016 for buildings with typologies A and B are 155 kWh / m² and 129 kWh / m² respectively, while the average EUI of the group is 145 kWh / m². In addition, approximately 30% of the buildings analyzed have a EUI between 124 and 147 kWh / m², expected results according to the methodology defined by [10]. The average values indicate that type A consumes more energy than type B, because type A buildings have a higher percentage of glazing.

On the other hand, the analysis of the EUI, based on the real consumption of electrical energy in buildings,

determined that consumption decreases in 2017 with respect to 2016, as is shown in Fig. 8, because of the environmental temperatures in 2017 were lower than the year 2016. In addition, if there is no change in the type of use of the buildings, it is established that the environmental temperature influences the behavior and energy consumption.

Figure 7: Characterization of energy consumption

According to Fig. 8, it is defined that buildings that present EUI greater than 157 kWh / m², in meteorological conditions similar to 2017, are categorized as large energy consumers. Then, the groups of high and medium consumption are the buildings type A and the buildings type B have an architectural design which decreases the energy use. The main architectural differences are that Type A has a greater amount of glazing and also has 25m² more construction. On the other hand, Type B has a cover at the entrance door.

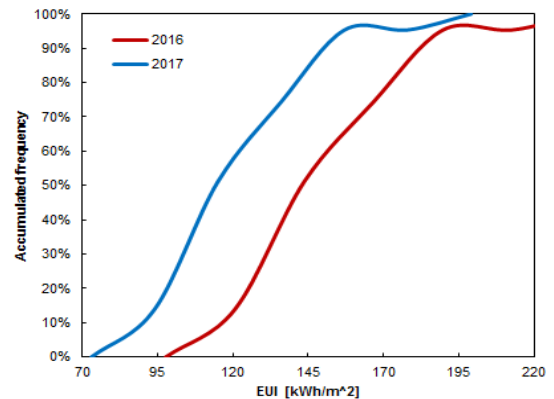

Figure 8: EUI Accumulated frequency analysis to 2016&2017

3.2 Energy simulation

For this research, a building type A was selected, which was simulated to get its energy behavior. In addition, it has an altitude of 9 m.a.s.l. which is the average altitude of the sample. Although, there is no relationship between the location of each building and the level of consumption. On the other hand, it is observed that the environmental temperature influences the energy consumption of all buildings for the 2016 and 2017 periods.

In Fig. 9 is observed that there is a growing relationship between electricity consumption and environmental temperature. The adjustment curve obtained shows that the energy consumed by the building presents a greater influence of the temperature from 26°C with an approximate consumption of 2 000 kWh.

Figure 9: Fitting curve, 24 months of actual energy and weather data of Building ideal

Subsequently, to validate the results obtained in Fig. 9. The energetic simulation of the ideal building was carried out with the previously established parameters. Fig. 10 shows the real energy consumption, simulated consumption and average environmental temperature for each month of 2016 and 2017. In addition, the behavior of cooling degree days (CDD) [15] is included to indicate the climatic conditions of the place. As a result, for the period established, it was obtained that the real and simulated energy behaviors are influenced by the required cooling loads as a consequence of the environmental temperature. In addition, a pattern of consumption is observed every six months which is repeated in the two years. Where the first semester of the

year presents higher consumption than the second as shown in Fig. 10.

It is expected that the CDD have a behavior similar to real and simulated consumption as well as the month of November 2017, where the three factors decrease at the same time. The differences between real and simulated consumption are due to the behavior and operation of the building itself as its operation and occupation, which vary during the year according to the dynamics of the city and climate variability. In the simulation, the occupation was constant depending on the employees who provide the public service. Finally, Fig. 10 shows that the basic consumption of buildings, consisting of the lighting system and electronic equipment, has a constant value over 1 000 kWh. The simulated average base consumption corresponds to 46% of the total consumption, while for the air conditioning system it is 54% noticing that the energy consumption is related by the climatic conditions.

It is expected that the CDD have a behavior similar to real and simulated consumption as well as the month of November 2017, where the three factors decrease at the same time. The differences between real and simulated consumption are due to the behavior and operation of the building itself as its operation and occupation, which vary during the year according to the dynamics of the city and climate variability. In the simulation, the occupation was constant depending on the employees who provide the public service. Finally, Fig. 10 shows that the basic consumption of buildings, consisting of the lighting system and electronic equipment, has a constant value over 1 000 kWh. The simulated average base consumption corresponds to 46% of the total consumption, while for the air conditioning system it is 54% noticing that the energy consumption is related by the climatic conditions.

Figure 10: Real consumption, simulation consumption and CDD, results

3.3 Energy monitoring

To validate the energy simulation, real energy consumption data of a UPC was collected for April and May, each 15 minutes. The energy consumption of the air conditioning systems accounted for 57.4% of the total building consumption. The remaining 42.6% corresponds to equipment with energy requirements independent of external climatic conditions, such as servers, lighting, printers, and other devices. These values exhibit an error of less than 5% compared to the results obtained from the energy simulation.

Using heat maps, the monitored monthly consumption patterns of the UPC were identified as shown in Fig. 11. Cool colors (shades of blue or light blue) indicate low-value ranges, while warm colors (shades of yellow or red) indicate high values within a given scale. It is observed that consumption does not depend on the day of the week but rather on the occupancy schedule.

The typical consumption schedule during a workweek is from 9h00 to 10h00, with elevated consumption observed. The periods of highest consumption are approximately from 12h00 to 18h00. Due to the activities carried out in the UPC, the building is occupied by staff 24 hours a day, 7 days a week. For this reason, it is not possible to define a specific start or end time for the workday. However, it is observed that

from 22h00 to 8h00, most equipment, including the air conditioning, is turned off.

3.4 Identification of savings opportunities

Strategy 1

As shown in Fig. 11, the activation and deactivation of the air conditioning system are not automatic. The system is fully activated between 8h00 and 22h00, with 9h00 being the most frequent activation time. The system is deactivated between 21h00 and 12h00, and in some cases at 2h00. The building does not exhibit any difference in energy consumption on weekends compared to weekdays. However, from 22h00 until 9h00, it shows a similar hourly energy usage pattern during the week, amounting to 4.5 kWh

In this regard, an energy-saving strategy is proposed, which involves gradually activating the air conditioning system starting at 9h00 and deactivating it at 20h00. These two events must be carried out with the exterior doors completely closed to control internal thermal load.

When applying the described strategies, a minimum estimated monthly savings of approximately 9% is anticipated, equivalent to 10 322 kWh per year, 3.8 metric tons of CO₂ emissions [18] and 743 USD considering the current rate [17].

Figure 11: Average real consumption of the building

Strategy 2

The electrical consumption of the air conditioning system is highly influenced by external environmental conditions. This allows for the determination of potential savings through the adjustment of the minimum operating temperature of the air conditioning system.

The analysis of Cooling Degree Days (CDD) showed that 22°C is the minimum activation temperature for the air conditioning system. By increasing the control temperature to 23°C, an approximate electricity saving of 16.83% of the system's consumption is expected, amounting to 478 kWh per month, 413 USD per year considering the current rate [17], and 1.4 metric tons of CO₂ emissions [18].

In Table 3, the percentage increase or decrease in monthly consumption of the air conditioning system is presented when reprogramming the system's operating temperature. The values presented were determined based on the consumption data for April and May and may vary in different seasons with different climate control requirements.

Table 3: Energy savings percentages based on changes in the on-off configuration

°C	T20	T21	T22	T23	T24
T20	0.00%	-9.13%	-14.05%	-27.92%	-40.97%
T21	11.97%	0.00%	-14.05%	-21.21%	-35.94%
T22	23.92%	14.05%	0.00%	-16.83%	-32.65%
T23	35.71%	27.92%	16.83%	0.00%	-20.04%
T24	46.81%	40.97%	32.65%	20.04%	0.00%

Table 4 shows the forecasted savings for both strategies.

Table 4: Results of strategies 1 and 2

Saving	Energy	Emission	Economic
Strategy 1	10 322 kWh	3.8 mtCO ₂	743 USD
Strategy 2	478 kWh	1.4 mtCO ₂	413 USD
Total	10 800 kWh	5.2 mtCO ₂	1 156 USD

4. CONCLUSIONS

The selected sample consists of two types of buildings A and B, which differ by the construction area and the amount of glazing. The statistical analysis shows that the energy consumption of buildings is influenced by temperature. It has been determined that the year 2016 had a higher temperature than 2017. Furthermore, the analysis of degree days of refrigeration confirms that Guayaquil city belongs to the very hot humid zone.

Within 43 buildings, 4 buildings form the group of high consumption during the two years, which

corresponds to 13% of total energy consumption of the sample. If the 4 buildings had the energetic behavior of building type A, an approximate saving of 2 000 USD per building would be obtained. With this value it is possible to pay 90% of annual electric service of the monitored building.

The analyses on the UPC type A shows that the variables considered in the simulation (envelope, activity, use, equipment, etc.) are adapted to the real energy behavior. When UPC uses electrical energy only for base loads, electricity consumption is not influenced by weather conditions.

Real information was collected on the disaggregated energy consumption of a UPC to understand its energy behavior and in this way identify savings opportunities and optimize energy use in similar buildings in the same climatic zone.

Reducing the control temperature of the cooling system by 1°C has the potential to yield annual savings of 413 USD. Additionally, optimizing and automating the activation and deactivation of the cooling system can lead to savings of 743 USD per year

5. ACKNOWLEDGMENT

This work was fully supported by the Regulation and Control Agency for Energy and Non-Renewable Natural Resources (ARCERNNR), Geological and Energy Research Institute (IIGE), National Police of Ecuador, and Spanish Agency for International Development Cooperation (AECID)

Catalina Vallejo Coral.- She was born in Quito, Ecuador, in 1986. She received her degree in Mechanical Engineering from the Escuela Politécnica Nacional in 2011, and her Master of Science with a specialization in Energy Engineering from Tecnológico de Monterrey, Mexico, in 2017. Her research fields are related to energy efficiency, simulation, thermal comfort, and energy management in buildings and industry. Currently, she is a researcher at the Instituto de Investigación Geológico y Energético.

Felipe Godoy.- Originating from Quito, Ecuador, he holds a Bachelor's degree in Mechanical Engineering and is currently pursuing a Master's in Chemical and Energy Engineering at Otto-von-Guericke University Magdeburg (OVGU). With experience as a Scientific Researcher at the Instituto de Investigación Geológico y Energético, he specialized in energy efficiency in buildings, energy simulations and he had international project collaboration, with proficiency in simulation tools, data analysis, and research. Other experiences include an internship at German Aerospace Center (DLR), focusing on conceptual models for electrochemical systems, and as a researcher assistant at OVGU, conducting thermal simulations and packing beds. Proficient in MATLAB and Python, they excel in modeling and analysis, enhancing his expertise in electrochemical systems and thermal simulations.

Francis Vásquez.- He was born in Ecuador. He completed his bachelor's in Mechanical Engineering from the Escuela Politécnica Nacional in 2016 and his M. Eng in Energy Conversion Systems and Technologies from the Rovira i Virgili University in 2020.

He worked for five years as a research assistant at the Instituto de Investigación Geológico y Energético in Quito, Ecuador. His main research focus was developing thermal characterization of phase change materials and thermal energy simulation in building applications. Currently, he is a graduate student in the University of Connecticut working in the Nanoscale Imaging and Transport (NIT) Lab where develops thermal transport solutions for micro and nanoscale semiconductor devices.

Geovanna Villacreses.- She is a Geographic and Environmental Engineer, graduated from the Master of Science in Geographic Information Systems program at the University of Salzburg. Since 2014, she has conducted research in the field of energy efficiency in

buildings and the application of multi-criteria methods for site selection with renewable potential in the country. She is currently working at the “Instituto de Investigacion Geologico y Energetico” as Director of Innovation.

Marco Orozco.- He was born in Tulcán and grew up in Quito, Ecuador. He completed his undergraduate studies in Automotive Engineering at the “Universidad de las Fuerzas Armadas” and his postgraduate studies at the “Escuela Politécnica

Nacional” in the Master's program in Design, Production, and Industrial Automation. He currently works as a Technical Analyst at the “Instituto de Investigación Geológico y Energético”. He has experience in the development of projects related to Energy Efficiency and Renewable Energies.

Santiago Navarro Vélez.- He was born in Quito, Ecuador, in 1996. He obtained his degree in Mechanical Engineering from the "Escuela Politécnica Nacional" in 2021. Currently, he works as a research assistant at the "Instituto de Investigación Geológico y

Energético" in the area of Innovation and Scientific Management. His research focuses on thermal energy simulation in buildings, thermal comfort and energy efficiency.
